NATIONAL MARINE FISHERIES SERVICE APPLICATION INSTRUCTIONS FOR PERMITS FOR THE INCIDENTAL TAKE OF ENDANGERED OR THREATENED SPECIES UNDER THE ENDANGERED SPECIES ACT In coordination with, but not substituting for 50 CFR 222.307 OMB control number (0648-0230) Expiration date for clearance: 03/31/2012

Information Required in the Application

The Assistant Administrator may issue permits to take endangered or threatened marine species incidentally to an otherwise lawful activity under section 10(a)(1)(B) of the Endangered Species Act of 1973 (ESA). The information collection associated with the following application instructions is required for the purpose of obtaining such a permit. The information provided will be used to process the incidental take permit in accordance with the ESA, including the solicitation of public comments on the justification of the take of ESA-listed species incidental to proposed activities. The information provided by an applicant in accordance with these instructions is not confidential and is subject to public exposure for comments. Notwithstanding any other provision of the law, no person is required to respond to, nor shall any person be subject to a penalty for failure to comply with, a collection of information displays a currently valid OMB Control Number. Public reporting burden for this collection of information is estimated to average 80 hours per response, including the time for reviewing instructions, searching existing data sources, gathering and maintaining the data needed, and completing and reviewing the collection of information. Send comments regarding this burden estimate or any other aspect of this collection of information, including suggestions for reducing this burden, to the address below.

An application for a permit should provide all of the following information. The information needed in the application should be presented in the same structure and format shown below to increase processing efficiency. When a question does not apply, do not overlook the category, but indicate Not Applicable (N.A.). In some cases, a brief explanation as to why the category is not applicable may expedite processing. Please note that for the title and closing statement of the application, specific wording is required.

If the applicant represents an individual or a single entity, such as a corporation, the application should be for an individual incidental take permit. If the applicant represents a group or organization whose members conduct the same or a similar activity in the same geographical area with similar impacts on endangered or threatened marine species, the application should be for a general incidental take permit. To be covered by a general incidental take permit, each individual conducting the activity must have a certificate of inclusion issued under paragraph (f) of 50 CFR 222.307. NMFS estimates a public reporting burden of .5 hour for each certificate of inclusion. The sufficiency of applications will be determined by the Assistant Administrator in accordance with the requirements of 50 CFR 222.307.

I. One of the titles below as appropriate:

A. Application for an Individual Incidental Take Permit under the Endangered Species Act of 1973.

Dan Forster or Director, Wildlife Resources Division Georgia Department of Natural Resources 2070 U.S. Hwy 278 SE Social Circle, GA 30025 Spud Woodward Control Constal Resources Division Georgia Department of Natural Resources One Conservation Way Brunswick, GA 31520

B. Application for a General Incidental Take Permit under the Endangered Species Act of 1973.

II. Date of the application.

February 27, 2012

III. The name, address, telephone, and fax number of the applicant. If the applicant is a partnership, corporate entity or is representing a group or organization, include applicable details.

Dan Forster (770-918-6400) and/or Spud Woodward (912-264-7218) See above for respective addresses

IV. A description of the endangered or threatened species, by common and scientific name, and a description of the status, distribution, seasonal distribution, habitat needs, feeding habits and other biological requirements of the affected species.

Refer to previously provided report "Altamaha Sturgeon-Section 6 Final Report (Bahn and Peterson, 2010)".

- V. A detailed description of the proposed activity, including, but not limited to:
 - A. The anticipated dates and duration of the activity.

GA commercial shad season dates can be found on pages 17-18 of "Georgia's Commercial Saltwater Fishing Regulations" that was previously provided. GADNR request that this permit be valid for a term of 10 years beginning January 1, 2012.

B. The specific location of the activity. Please include latitude/longitude coordinates if possible.

Waters open to commercial shad fishing can be found on pages 17-18 of "Georgia's Commercial Saltwater Fishing Regulations" that was previously provided.

C. For a general incidental take application, include an estimate of the total level of activity expected to be conducted.

According to mandatory individual records (trip tickets) reported to GADNR Coastal Resources Division (CRD), from 2007 through 2011 total statewide annual commercial shad fishing trips in GA have declined from 388 trips to 241 trips/yr and averaged 316 trips/yr during this time. GADNR anticipates that commercial fishing activity will remain stable or slightly decline over the duration of the requested permit.

- VI. The application must include a conservation plan based on the best scientific and commercial data, which specifies:
 - A. The anticipated impact of the proposed activity on the listed species, including:
 - 1. The estimated number of animals of the listed species and, if applicable, the subspecies or population group, and range.

Estimated total number of shortnose sturgeon incidentally captured by shad set-net fishermen in the Altamaha River ranged from 53-498 fish during 2007-2009 (Bahn and Petereson, 2010). This same study also estimated the Altamaha River population at approximately 6,300 fish. New commercial shad regulations that were instituted January 1, 2011 should substantially reduce incidental bycatch of sturgeon since these rules closed the section of the Altamaha River with the highest bycatch rates. Bahn and Peterson (2010) stated "In fact, we estimate that more shortnose sturgeon were incidentally captured in the upper river during January 2009 (333 fish) than in all months of all three years combined in the lower river (216 fish; Table 2)". For the section of the Atlamaha that is currently open to commercial shad fishing, this study reported that during 2007-2009 the highest total annual bycatch of sturgeon by fishermen was estimated at 111 fish. GADNR also records incidental sturgeon captures while conducting an American shad fishery independent gill net survey on the Altamaha River and from 2001-2010 a total of 73 shortnose sturgeon were captured and released alive. The catch rate of shortnose sturgeon from the American shad gill net survey averaged 0.41 fish/day over this 10-yr period. During this same 10-yr period, the highest catch rate from any consecutive 3-year period (2001-2002) was 0.94fish/day. These catch rates were significantly impacted by one year in which 41 of the 73 shortnose sturgeon were captured. Other than 2002, the highest number of shortnose sturgeon captured during the GADNR gill net survey in one year was 8 fish. From 2001-2010, reported commercial shad fishing trips on the Altamaha River averaged 265 trips. Utilizing catch rates from the GADNR gill net survey resulted in an estimated range of 109-250 shortnose sturgeon being incidentally captured per year in the commercial shad fishery. Due to the high variability in shortnose sturgeon bycatch rates, GADNR proposes utilizing 3-year running averages to monitor shortnose sturgeon bycatch. GADNR estimates that 3-year averages of incidental bycatch will not likely exceed 175 fish/yr in the Altamaha River.

Bahn and Peterson observed extremely low catch rates of Atlantic sturgeon in the commercial shad fishery during their 2007-2009 study, with only 6 Atlantic sturgeon being captured over the entire 3-year study. Due to the low catch rates an accurate estimate of total Atlantic sturgeon incidental capture could not be produced from the 2007-2009 study (personal comm). GADNR does record incidental Atlantic sturgeon captures while conducting an American shad fishery independent gill net survey on the Altamaha River and from 2001-2010 a total of 33 Atlantic sturgeon were captured and released alive. All of these were sub-adult fish with an average total length of 526 mm. The catch rate of Atlantic sturgeon from the American shad gill net survey averaged 0.19 fish/day over this 10-yr period. During this same 10-vr period, the highest catch rate from any consecutive 3-year period (2006-2008) was 0.41fish/day. From 2001-2010, reported commercial shad fishing trips on the Altamaha River averaged 265 trips. Utilizing the catch rate of 0.41 fish/day results in an estimate of 109 Atlantic sturgeon being incidentally captured per year. Based on this data, GADNR estimates that 3-year averages of incidental bycatch will not likely exceed 140 fish/yr in the Altamaha River.

A similar study was completed on the Savannah River in the 1990's. Collins et al. (1996) reported that during the 1990-92 shad seasons a total of 240-shortnose sturgeon were captured by Savannah River shad fishermen. The Savannah River is open to commercial shad fishing from U.S. Hwy 301 (rkm 192), downstream to the Atlantic Ocean, an area approximately 103 rkm or 35% smaller than previously open to commercial shad fishing. Closing the upper portion of the river should decrease incidental bycatch and protect suspected spawning sites. It is estimated that 3-year averages of shortnose sturgeon incidental bycatch by GA shad fishermen will not exceed 75 fish/yr in the Savannah River.

GADNR does not conduct a fishery independent gill net survey on the Savannah River and does not have any recent data regarding the incidental bycatch of Atlantic sturgeon by the commercial shad fishery for the Savannah River. Therefore, GADNR proposes utilizing bycatch rate developed from the Altamaha fishery independent gill net survey to estimate the anticipated number of Altantic sturgeon that may be intercepted in the Savannah River. From 2001-2010, Savannah River commercial shad fishing effort reported to GADNR has averaged an estimated 85 trips/yr. Utilizing the catch rate of 0.41 fish/day derived from the Altamaha River results in an estimate of 35 Atlantic sturgeon being incidentally captured per year. Based on this data, GADNR estimates that 3-year averages of incidental bycatch will not likely exceed 50 fish/yr in the Savannah River.

Incidental bycatch of sturgeon by the commercial shad fishery has not been evaluated in the Ogeechee River. This is a very small commercial fishery and based on the total number of commercial shad fishing trips from 2007-2011, approximately 2% of the total statewide effort is exerted on the Ogeechee River. New regulations closed approximately 137 rkm or 66% of the river previously open to commercial fishing and also limited legal gear to drift nets only. GADNR believes that 3-year averages of incidental bycatch will likely not exceed 10 shortnose and 10 Atlantic sturgeon/yr in the Ogeechee River.

2. The type of anticipated taking, such as harassment, predation, competition for space and food, etc.

GA commercial regulations require that all sturgeon incidentally captured must be immediately released unharmed (pg 18 "Georgia's Commercial Saltwater Fishing Regulations")

3. The effects of the take on the listed species, such as descaling, altered spawning activities, potential for mortality, etc.

Bahn and Peterson (2010) reported a very low mortality rate of 2.3% for shortnose sturgeon that were captured in set nets targeting American shad in the Altamaha River. Sub-lethal effects are unclear.

B. The anticipated impact of the proposed activity on the habitat of the species and the likelihood of restoration of the affected habitat.

The American shad gill net fishery is a low impact fishery and should have extremely minor physical affects on aquatic habitat utilized by shortnose sturgeon. In addition, the newly established commercial fishery boundaries will provide protection to confirmed and suspected spawning sites in Georgia's rivers.

- C. The steps that will be taken to monitor, minimize, and mitigate such impacts, including:
 - 1. Specialized equipment, methods of conducting activities, or other means.

Refer to page 18 of "Georgia's Commercial Saltwater Fishing Regulations" for information on legal shad fishing gear.

2. Detailed monitoring plans.

See monitoring plan document that was previously submitted.

3. Funding available to implement measures taken to monitor, minimize and mitigate impacts.

In 2011, Georgia Department of Natural Resources management and monitoring of commercial fisheries operated under state appropriations and federal awards totaling approximately \$180,000. GADNR is mandated by ASMFC to annually monitor commercial shad fisheries and sturgeon populations. GADNR will utilize state appropriated funds, federal awards and existing staff to monitor the commercial shad fishery and incorporate sturgeon bycatch monitoring.

D. The alternative actions to such taking that were considered and the reasons why those alternatives are not being used.

See alternative regulation document that was previously submitted.

E. A list of all sources of data used in preparation of the plan, including reference reports, environmental assessments and impact statements, and personal communications with recognized experts on the species or activity who may have access to data not published in current literature.

Bahn and Peterson (2010) Collins et al (1996) GA Commercial Saltwater Fishing Regulations GADNR (personal comm.)

An application for a certificate of inclusion under a General incidental take permit must include the following:

- 1. General incidental take permit under which the applicant wants coverage;
- 2. Applicant's name, address and telephone number (if the applicant is a partnership or corporate entity, then the applicable details);
- Description of the activity the applicant wants covered under the general permit, including anticipated geographic range and season; and
- 4. Signed statement that the applicant has read and understood the general incidental take permit and the conservation plan, will apply with the applicable terms and conditions, and will fund the applicable measures of the conservation plan.

Modifications to Permits

Requests for modifications to incidental take permits should address all applicable sections of these instructions, including a detailed description of the proposed changes. Appropriate changes should also be made to the Conservation Plan. Modification requests involving an increased number of animals, additional species, an increased risk to the animals, or a significant change in the location of incidental take are subject to the 30-day public review and are granted or denied at the discretion of the Assistant Administrator for Fisheries.

Where to Send the Application

The application may be submitted electronically, if possible (either by email or by mailing a disk), but one signed original of the complete application must be sent to one of the following addresses.

Send applications for incidental take of all species except sea turtles and Pacific salmon to:

Chief, Endangered Species Division National Marine Fisheries Service, F/PR3 1315 East-West Highway Silver Spring, Maryland 20910 Telephone 301-713-1401 Fax 301-713-0376

Send applications for incidental take of sea turtles to:

Chief, Marine Mammal and Turtle Division National Marine Fisheries Service, F/PR2 1315 East-West Highway Silver Spring, Maryland 20910 Telephone 301-713-2322 Fax 301-713-4060 Web Site http://www.nmfs.noaa.gov/pr/

Please see separate application instructions for incidental take permits for sea turtles, available on-line at http://www.nmfs.noaa.gov/pr/permits/esa_permits.htm

Send applications for incidental take of anadromous fish in the Pacific to one of these offices:

Pacific Salmon Northwest Regional Office National Marine Fisheries Service 7600 Sand Point Way NE Building 1 Seattle, WA 98115 Phone: (206) 526-6150 Fax: (206) 526-6426

NMFS Northern California Coast Salmon National Marine Fisheries Service 1655 Heindon Road Arcata, CA 95521 Phone: (707) 825-5163 Fax: (707) 825-4840

NMFS Central California Coast Salmon National Marine Fisheries Service 777 Sonoma Ave., Room 325 Santa Rosa, CA 95404 Phone: (707) 575-6050 Fax: (707) 578-3435

GA American Shad Fishery Sturgeon Bycatch Monitoring Plan

The Georgia Department of Natural Resources (GADNR) proposes to utilize a combination of a trip ticket system and direct observations to monitor the bycatch of shortnose sturgeon in the commercial shad fishery. Georgia regulations currently require commercial fishermen to complete trip tickets to document species, sex and pounds of shad harvested each day. In addition to the information on shad harvest, these tickets capture the fisherman's name and license number, name of dealer that purchases fish, river fished, gear type (set or drift net), length of net, total soak time, and number of net sets. Fishermen and/or dealers are required to return completed trip tickets to the Georgia Department of Natural Resources by the 10th of each following month (i.e. January tickets would be due by February 10). The current trip ticket will be modified to require fisherman to record information on sturgeon bycatch (total numbers of sturgeon interactions with the shad fishery. Modified trip tickets will have rows and/or columns for fishermen to separately record incidental catches of shortnose and Atlantic sturgeon.

GADNR will make a concerted effort to educate commercial shad fishermen on the importance of both accurately recording sturgeon incidental catches and returning the trip tickets in a timely manner, at least by the 10th of each following month. GADNR will develop an informational packet on sturgeon identification, proper handling (emphasizing the importance of fishermen frequently checking their nets and immediately releasing any sturgeon that are incidentally caught), and the importance of reporting incidental sturgeon catches. Prior to each shad season, this informational packet will be provided to all known commercial shad fishermen.

A list of names and addresses of commercial shad fishermen will be compiled from prior trip tickets, the commercial fishing license database, and a list of cooperators in shad tagging studies. A set of trip tickets, self-addressed return envelopes, and information on how to obtain additional trip tickets will also be provided to each fisherman on this list. In addition to these direct handouts and mailings, GADNR Law Enforcement staff will be supplied additional trip tickets to be provided to shad fishermen encountered during routine patrol.

According to results reported by Bahn and Peterson (2010), estimated shortnose sturgeon bycatch determined from direct observations of commercial shad fishing activities did not differ significantly from those estimated from commercial shad fishermen log book data for the same time period. However, GADNR believes that it is still important to periodically observe commercial shad fishing activities. Thus, GADNR staff will utilize the same list of names obtained from trip tickets, the commercial fishing license database, and the list of cooperators in shad tagging studies to establish contact information (i.e. phone numbers) for a subset of individuals that commercially fish for shad on the Altamaha, Ogeechee, and Savannah rivers.

Once contact information has been established for a set of fishermen for each river, GADNR staff will contact fishermen to determine when they will be fishing and to establish a time and location to observe fishermen pulling their nets. The goal will be to make observations within 24-48 hours of contact with the fisherman. Numbers of direct observations for each river will be based on current shad fishing pressure and spawning migrations of shad and sturgeon.

GADNR will attempt to observe a minimum of 10% of the commercial shad fishing trips on each river. Based on averaging the last 3 years of commercial fishing effort, GA DNR would need to observe approximately 25, 5, and 1 trip each year, respectively, for the Altamaha, Savannah, and Ogeechee rivers. Since commercial shad fishing effort is extremely low on the Ogeechee River, GADNR will attempt to observe at least 2 trips per year on the Ogeechee River.

Monthly observations for a river system may also vary. Shad fishing effort is typically lower on all three rivers in January than in February and March due to the fact that shad abundance is less early in the season. Therefore, the number of direct observations will likely be lower for January than for the following months.

GADNR monitors the shad spawning migration every week during the commercial shad season, which allows staff to know when the spawning run and resulting fishing pressure are peaking. This information will allow GADNR to make necessary adjustments in monitoring efforts to ensure that at least 10% of all commercial shad fishing trips are observed annually. Monitoring efforts will also be adaptive to the timing of the sturgeon spawning migration and the number of sturgeon intercepts. GADNR will increase direct observations if high numbers of sturgeon intercepts are detected. GADNR is confident that this approach will ensure that an adequate number of observations are made during the peak of both the shad and sturgeon spawning migrations so that sturgeon bycatch is accurately estimated.

If unusually high catch rates are being observed, GADNR will immediately increase law enforcement presence and educational efforts. Staff will also begin evaluating additional modifications to the commercial shad fishing regulations for the next year. Data collected from the trip tickets and direct observations will be summarized and provided to the National Marine Fisheries Service no later than the end of February, March, and April each year.

¹ Bahn, R. A., D. J. Farrae, and D. L. Peterson *in part to be submitted to* Reviews in Fish Biology and Fisheries summer 2010

The shortnose sturgeon, Acipenser brevirostrum LeSueur 1818, is the 22 23 smallest member of Acipenseridae, and inhabits coastal rivers and estuaries 24 along the Atlantic Coast of North America from the St. John River, Canada, to the 25 St. John's River in northeast Florida (Vladykov and Greeley 1963; Moser and 26 Ross 1995; Bain et al. 2007). Like other members of the genus, shortnose 27 sturgeon are long-lived, late maturing, diadromous fishes with a protracted 28 spawning periodicity (Vladykov and Greeley 1963; Bemis and Kynard 1997). 29 Historical abundance estimates are scarce, however, shortnose sturgeon were 30 exploited for decades along with the sympatric Atlantic sturgeon, Acipenser 31 oxyrinchus (Smith et al. 1984). During the last century, shortnose sturgeon had 32 become sufficiently rare that they were listed as an endangered species in the 33 United States in 1967 (National Marine Fisheries Service (NMFS) 1998). Today, few healthy populations exist and many anthropogenic factors impede restoration 34 35 efforts (Kynard 1997). Many populations, particularly in southern rivers, continue 36 to be threatened with extinction. With federal protection in place, the two primary 37 factors currently affecting population recovery in the Southeastern U.S. are 38 habitat degradation and fishing mortality as a result of unintended capture or 39 "bycatch" in commercial fisheries targeting other species (Collins et al. 2000).

40

41 Life History

Sturgeon are long-lived, late maturing, diadromous fishes with a
 protracted spawning periodicity (Bemis and Kynard 1997). Populations of
 shortnose sturgeon have life history differences in their northern and southern

ranges, but southern populations have not been well studied. In southern rivers, 45 46 shortnose sturgeon mature sooner, spawn earlier in the year, grow faster, and 47 have shorter life spans compared to those in the northern part of the range (Vladvkov and Greelev 1963; Heidt and Gilbert 1978; Dadswell 1979). 48 As an amphidromous species, shortnose sturgeon require riverine habitats 49 50 to complete their life cycle, but they will migrate to estuarine and marine habitats 51 for purposes other than spawning (Bemis and Kynard 1997). Shortnose 52 sturgeon typically mature at 500-600 mm total length (TL), which is reached by 2-53 3 years for males and 3-5 years for females in southern populations (Dadswell 54 1979; Kynard 1997). After maturity, males spawn every 1-2 years; females 55 spawn every 3-5 years (Dadswell 1979). Southern shortnose sturgeon are 56 estimated to live less than 20 years, compared to 30-67 years for their northern 57 counterparts (Rogers and Weber 1994; Kynard 1997). Spawning occurs from 58 late January (D. Peterson, unpublished data) to March in southern rivers, where 59 shortnose sturgeon migrate to the upstream portion of their population range 60 (Heidt and Gilbert 1978; Bain 1997; Kynard 1997). In the Altamaha River, 61 spawning is thought to occur between river kilometer (rkm) 167 and 215 (DeVries 2006; D. Peterson, unpublished data). 62

63

64 Bycatch

Fishing mortality from bycatch is a problem for many species that have life
histories dependent on late maturation and protracted spawning periodicity
(Boreman 1997; Stein et al. 2004). Although they are long-lived, sturgeons only

spawn once every 3-5 years (Dadswell 1979). Hence, sturgeon populations are
especially sensitive to loss of reproductive potential from bycatch mortality
(Boreman 1997).

Bycatch of sturgeon in riverine, estuarine, and marine fisheries is a threat to the recovery of many sturgeon populations (Stein et al. 2004; Munro et al. 2007). Although shortnose sturgeon are federally protected, they are frequently captured across their range in commercial fisheries targeting other riverine species (Kynard 1997). Most of this bycatch occurs in anchored and drifted gill net fisheries for American shad (*Alosa sapidissima*; Collins et al. 1996; Kynard 1997).

78 Bycatch of shortnose sturgeon by commercial shad fisheries is well 79 documented (Heidt and Gilbert 1978; Dadswell 1979; Collins et al. 1996; Weber 80 1996; Kynard 1997; Collins et. al 2000). Collins et. al (2000) states that the use of anchored gill nets in essential habitats by commercial fishermen is a threat to 81 82 the recovery of sturgeon populations. In Georgia, commercial shad fisheries are 83 open from January 1 to March 31. Based on total fishing effort, the shad fishery 84 is one of the largest commercial fisheries operated in Georgia (Collins et al. 85 1996). Adult shortnose sturgeon are vulnerable to incidental capture by 86 commercial shad fisheries because their upstream spawning migration coincides 87 with the peak commercial fishing effort (Collins et al. 2000). Soak time directly 88 affects sturgeon mortality rates in anchored gill net fisheries (Atlantic Sturgeon 89 Status Review Team (ASSRT) 2007). In the Altamaha River, commercial 90 fishermen use both drifted and anchored gill nets in different portions of the river.

91 Anchored gill nets must have a minimum of 11.43 cm stretched mesh with a 92 maximum length of 30.48 m. Nets must be spaced at least 182.88 m apart with 93 one end attached to the shore, allowing open fish passage through at least 1/2 of 94 the river channel. Most gill nets deployed upstream of the estuary in the 95 Altamaha River from 2004-08 were anchored gill nets (D. Peterson, unpublished 96 data). Drifted gill nets can be used throughout the river, but are mostly used in 97 the estuary. Only drifted gill nets are permitted in the Altamaha Sound. Collins 98 et al. (1996) and Stein et al. (2004) state that the time non-target species spend 99 tangled in drifted gill nets is likely less than that of anchored gill nets because 100 drifted gill nets must be tended constantly to prevent these nets from becoming 101 entrained on benthic debris. Collins et al. (1996) also states that catch per unit 102 effort (CPUE) of sturgeon may be lower in drifted gill nets because they often do not fish the lower portion of the water column. 103

Previous studies of shad fisheries have shown that shortnose sturgeon bycatch can be significant. Collins et al. (1996) reported that shad fishermen captured 240 shortnose sturgeon from 1990-92 in the Savannah River. In this study, 97% of captured shortnose sturgeons were mature adults (TL 560 -1060 mm). In 1994, the shortnose sturgeon population in the Savannah River was calculated to be 1676, but this estimate was deemed incorrect because not all assumptions of the Schnabel model were met (NMFS 1998).

Both shortnose sturgeon and American shad migrate to upstream
spawning sites in southern rivers during February and March (Hall et al. 1991;
Collins and Smith 1995). Spawning shortnose sturgeon leave the estuary in mid-

114 December, migrating upstream for several hundred kilometers throughout the 115 winter (DeVries 2006). Although Georgia's commercial shad fishery does not 116 open until January. DeVries (2006) documented adult shortnose sturgeon 117 continuing upstream migrations throughout February and early March. Hence, 118 the temporal and spatial overlap of shortnose sturgeon migrations and the 119 commercial fishery creates a potential for incidental capture of spawning 120 shortnose sturgeon. Although commercial fishermen must immediately release 121 any sturgeon caught, soak time of commercial gear is not regulated. 122 Consequently, most commercial fishermen check their nets once daily, thereby 123 increasing the potential for injury or death of entangled shortnose sturgeon. 124 Aside from direct mortality caused by long soak times of anchored gill nets, 125 prolonged entanglement of sturgeon can have sublethal effects, but they have 126 not been well studied (Moser and Ross 1995; Boreman 1997; Kynard 1997). 127 Previous studies have reported instances where radio-tagged shortnose 128 sturgeon aborted their spawning migrations after being captured in commercial 129 anchored gill nets (Moser and Ross 1995; Weber 1996). 130 Mortality and injury of sturgeons because of bycatch in shad fisheries has 131 been identified as a serious threat to southern sturgeon populations (Kynard 132 1997; Collins et al. 2000). Because the Altamaha River contains the largest 133 population of adult shortnose sturgeon (~1800 individuals) south of the Delaware 134 River, bycatch of shortnose sturgeon in the shad fishery is a concern to both 135 state and federal agencies (NMFS 1998; DeVries 2006). The observed mortality 136 rate of over 30% in the Altamaha River shortnose sturgeon population (DeVries

2006) is high compared to 22% in the Hudson River (Secor and Woodland 2005).
The effect of bycatch on the mortality rate of shortnose sturgeon in the Altamaha
River is unknown; however, Collins et al. (1996) documented a 16% mortality
rate and a 20% injury rate among shortnose sturgeon captured in the commercial
shad fishery of Winyah Bay, SC.

142

143 **Research Objectives and Justification**

144 The objective of my study was to estimate the bycatch of shortnose 145 sturgeon in the commercial shad fishery of the Altamaha River, GA. The 146 National Marine Fisheries Service has identified studies of shortnose sturgeon 147 bycatch in commercial fisheries as a research priority throughout the Atlantic 148 Coast (NMFS 1998). In a previous study of shortnose sturgeon bycatch in the 149 Savannah River, Collins et al. (1996) recommended the use of a standardized 150 creel survey methodology for future assessments in other southern rivers. 151 Because the effects of sturgeon bycatch have not been well studied, little is 152 known about how Georgia's commercial shad fisheries may be affecting recovery 153 of shortnose sturgeon throughout the state. Although surveys conducted during 154 the 1980s and 1990s documented mortality of shortnose sturgeon in Georgia's 155 shad fisheries, the population level effects were difficult to quantify because 156 shortnose sturgeon abundance estimates were not available (Collins et al. 1996). 157 A recent study by DeVries (2006) however, reported new abundance estimates 158 for Altamaha River shortnose sturgeon, providing a context for quantifying the 159 effects of bycatch. The results of this study provide the first quantified estimates

295 Abstract

296 Although the shortnose sturgeon (Acipenser brevirostrum) has been 297 federally protected as an endangered species since 1967, incidental capture of 298 shortnose sturgeon in commercial shad fisheries has been documented as a 299 source of mortality that may limit recovery of some populations. As such, 300 shortnose sturgeon by catch assessments were recently identified as a priority by 301 the National Marine Fisheries Service, as part of the iterative process of 302 identifying and reducing threats to East Coast sturgeon. The objective of our 303 study was to estimate total bycatch and mortality of shortnose sturgeon in the 304 anchored gill net portion of the Altamaha River commercial shad fishery from 305 2007 - 09. Using a roving creel survey design, we conducted on-the-water 306 counts of commercial shad nets to estimate fishing effort. Catch-per-unit effort 307 was estimated from log books and direct observations of net retrievals by 308 randomly selected commercial fishermen. During the 3 years of the study, total 309 estimated bycatch of shortnose sturgeon was 71, 53, and 498 fish, respectively. 310 Catch rates were highest during January and February of 2009 in upriver 311 commercial nets near previously confirmed spawning locations in the river. 312 Mortality of captured shortnose sturgeon was low in all three years (< 8%), 313 although we did not assess post-release survival. Future studies are needed to 314 better assess population level effects and sub-lethal effects of incidental capture 315 on shortnose sturgeon. Because bycatch is highly variable annually, future 316 studies need to be conducted over several seasons and throughout the extent of 317 the population range in a particular river.

318 Introduction

319 Shortnose sturgeon (Acipenser brevirostrum) are an amphidromous 320 species that ranges from the St. John River, Canada, to the St. John's River in 321 northeast Florida (Vladykov and Greelev 1963). Although shortnose sturgeon 322 were once common in most major East Coast river systems, commercial 323 exploitation and habitat degradation have reduced populations significantly 324 (Kynard 1997; Collins et al. 2000). The shortnose sturgeon has been federally 325 listed as an endangered species since 1967 (National Marine Fisheries Service 326 (NMFS) 1998). 327 Northern and southern populations of shortnose sturgeon are known to 328 exhibit several important differences in life history; however, southern 329 populations have not been well studied. In southern rivers, shortnose sturgeon

330 mature sooner, spawn earlier in the year, grow faster, and have shorter life spans

compared to those in the northern part of the range (Vladykov and Greeley 1963;

Heidt and Gilbert 1978; Dadswell 1979). As an amphidromous species,

333 shortnose sturgeon require riverine habitats to complete their life cycle, but they

will feed in estuarine and marine habitats during the winter months (Bemis and

335 Kynard 1997). Shortnose sturgeon typically mature at 500-600 mm total length

336 (TL), which is reached by 2-3 years for males and 3-5 years for females in

- 337 southern populations (Dadswell 1979; Kynard 1997). After maturity, males
- 338 spawn every 1-2 years; females every 3-5 years (Dadswell 1979). Southern

339 shortnose sturgeon are estimated to live less than 20 years, compared to 30-67

340 years for their northern counterparts (Rogers and Weber 1994; Kynard 1997).

Spawning occurs from late January (D. Peterson, unpublished data) to March in
southern rivers, where shortnose sturgeon migrate to the upstream portion of
their population range (Heidt and Gilbert 1978; Bain 1997; Kynard 1997).

344 Although shortnose sturgeon have been federally protected for more than 345 40 years, they are frequently captured across their range in commercial fisheries 346 targeting other riverine species (Kynard 1997). Most of this "bycatch" occurs in anchored and drifted gill net fisheries for American shad (Alosa sapidissima; 347 348 Collins et al. 1996; Kynard 1997). Several authors have shown that fishing 349 mortality from bycatch poses an especially serious threat to species with 350 reproductive strategies that depend on late maturation and protracted spawning 351 periodicity (Boreman 1997; Stein et al. 2004; Munro et al. 2007). Despite their 352 long life spans, shortnose sturgeon spawn only once every 2-5 years after reaching maturity (Dadswell 1979), making them particularly sensitive to the 353 354 cumulative losses of reproductive potential resulting from chronic bycatch 355 mortality (Boreman 1997).

356 Bycatch of shortnose sturgeon in commercial shad fisheries has been well 357 documented (Heidt and Gilbert 1978; Dadswell 1979; Collins et al. 1996; Weber 358 1996; Kynard 1997; Collins et. al 2000), but population level effects are poorly 359 understood. Previous studies of commercial shad fisheries have shown that 360 shortnose sturgeon bycatch can be significant and Collins et al. (2000) suggest 361 that this bycatch may be among the most serious impediments to the recovery of 362 southern shortnose sturgeon populations. In South Carolina, previous studies have shown that shad fishermen captured 240 shortnose sturgeon from 1990-92 363

in the Savannah River and that 97% of those captured were mature adults (TL
560 -1060 mm; Collins et al. 1996). In 1994, the shortnose sturgeon population
in the Savannah River was estimated at 1,676 individuals, suggesting that annual
bycatch in this commercial fishery may have resulted in the incidental capture of
up to 15% of the entire adult population.

Although shortnose sturgeon accidentally captured in commercial shad fisheries must be immediately released, delayed mortality and injury resulting from incidental capture has been identified as a serious threat to populations in

372 several southern rivers (Kynard 1997; Collins et al. 2000). Collins et al. (1996),

373 for example, documented a 16% mortality rate and a 20% injury rate for

374 shortnose sturgeon captured in commercial shad nets in Winyah Bay, SC.

375 In many Atlantic Coast rivers, spawning runs of American shad largely

overlap with those of shortnose sturgeon (Hall et al. 1991; Collins et al. 1996;

377 NMFS 1998). Consequently, adult shortnose sturgeon are particularly vulnerable

to incidental capture in commercial shad fisheries because their annual upstream

379 migrations coincide with the peak commercial fishing effort (Collins et al. 2000).

380 Because bycatch is a known problem for recovering shortnose sturgeon

381 populations, NMFS has identified studies of bycatch in commercial fisheries as a

research priority as part of the iterative process of identifying and reducing

threats to the recovery of sturgeons (NMFS 1998).

In Georgia, the Altamaha River contains the largest population of
shortnose sturgeon (~1,800 adults) within the southern portion of the range
(Peterson and DeVries 2006). Hence, bycatch of shortnose sturgeon in the

387 Altamaha commercial shad fishery is of particular concern to both state and 388 federal management agencies (NMFS 1998). In the Altamaha River, the 389 commercial shad fishery is open from 1 January to 31 March and fishermen may 390 use both drifted and anchored gill nets, depending on where they operate. 391 Drifted aill nets can be used throughout the river, but their use is largely restricted 392 to estuarine waters because of an abundance course woody debris above the 393 head of tide. Anchored cill nets can be used upstream of the estuary. Because 394 drifted nets must be tended constantly, the average duration of fish entanglement 395 is typically much lower in drifted nets compared to anchored nets (Collins et al. 396 1996; Stein et al. 2004). Collins et al. (1996) also noted that catch-per-unit-effort 397 (CPUE) of shortnose sturgeon may be lower in drifted gill nets because they 398 usually do not extend down to the benthos where shortnose sturgeon are 399 typically found. Anchored nets must have a minimum of 11.43-cm stretched 400 mesh with a maximum length of 30.48 m. Nets must be spaced at least 182.88 401 m apart with one end attached to the shore, allowing unhindered fish passage 402 through at least 1/2 of the river channel. Most gill nets deployed upstream of the 403 estuary in the Altamaha River from 2004-06 were anchored gill nets (D. 404 Peterson, unpublished data). 405 In southern rivers, both shortnose sturgeon and American shad migrate to 406 upstream spawning sites in southern rivers from December to March (Hall et al.

407 1991; Collins and Smith 1993; Bahn et al. 2010). Although Georgia's commercial

408 shad fishery does not open until January, DeVries (2006) documented adult

409 shortnose sturgeon moving upstream in December, and continuing their

410 migration through February and early March. Hence, the temporal and spatial 411 overlap of shortnose sturgeon spawning migrations and the commercial shad 412 fishery creates a potential for incidental capture of spawning shortnose sturgeon. 413 Soak time directly affects sturgeon mortality rates in anchored gill net fisheries 414 (Atlantic Sturgeon Status Review Team (ASSRT) 2007). Although commercial 415 fishermen must immediately release any shortnose sturgeon caught, soak time of 416 commercial gear is not regulated. Consequently, most commercial fishermen 417 check their nets only once daily, thereby increasing the potential for injury or 418 death of entangled shortnose sturgeon. Aside from direct mortality caused by 419 long soak times of anchored gill nets, sublethal effects of prolonged 420 entanglement have been documented for shortnose sturgeon (Moser and Ross 421 1995; Kynard 1997). Previous studies have reported several instances where 422 radio-tagged shortnose sturgeon aborted spawning migrations after capture in 423 anchored gill nets (Moser and Ross 1995; Weber 1996). 424 Because the effects of sturgeon bycatch have not been well studied, little 425 is known about how Georgia's commercial shad fisheries may be affecting 426 recovery of shortnose sturgeon throughout the state. The objective of our study 427 was to guantify bycatch of shortnose sturgeon in the anchored gill net 428 commercial shad fishery in the Altamaha River from 2007-2009. Although 429 surveys conducted during the 1980s and 1990s documented mortality of 430 shortnose sturgeon in Georgia's shad fisheries, the population level effects were 431 difficult to quantify because shortnose sturgeon abundance estimates were not 432 available (Collins et al. 1996). A recent study by Peterson and DeVries (2006)

433 however, provided new abundance estimates for Altamaha River shortnose 434 sturgeon, providing the key context necessary for quantifying the effects of 435 bycatch in this population. In this study, we report the first quantified estimates of 436 total bycatch and mortality rates of shortnose sturgeon in the Altamaha River 437 commercial shad fishery. The application of these results may provide an 438 important new framework for evaluating current commercial shad fishing 439 regulations in Georgia and on other rivers where shortnose sturgeon populations 440 coexist with commercial shad fisheries.

441

442 Study Site

443 The Altamaha River is formed on the coastal plain of Georgia by the 444 confluence of the Ocmulgee and Oconee rivers near Hazlehurst, GA (Figure 1). 445 The river flows southeast 215 km to the Atlantic Ocean near Darien, GA. The 446 watershed contains approximately 800 km of unimpounded channel habitat 447 accessible to diadromous fishes including shortnose sturgeon. Because the 448 stream drains over one-guarter of the state, channel depths are highly variable 449 depending on seasonal rainfall patterns and hydropower operation on reservoirs 450 in the Ocmulgee and Oconee rivers. The head of tide is typically located 451 between rkm 45-55, again depending on discharge. Mean channel depth is 452 typically 50-70 m in width and 2-3 m in depth (Heidt and Gilbert 1978). Depths 453 greater than 10 m are common in the tidally influenced section of the river. Deep 454 cutbanks (10 m and greater) and channel scours below bridges are found above 455 the head of tide.

456 Methods

457 Experimental Design

458 To estimate the number of shortnose sturgeon incidentally captured in the 459 commercial shad fishery, we conducted a standardized fishery assessment of the 460 Altamaha River mainstem from 1 January to 31 March, 2007-2009. Based on a 461 priori knowledge of known and suspected shortnose sturgeon spawning locations 462 (Peterson and DeVries 2006), we divided the river into two strata (Figure 1). The 463 upper river stratum began at rkm 215 and extended downstream to rkm 184. The lower river stratum began at rkm 184 and extended downstream to rkm 21. 464 Using a roving creel survey design (Malvestuto 1996), we conducted 465 466 weekly counts of anchored gill nets by traversing the entire 215 rkm of the study 467 area by boat. In 2007 and 2008, these weekly counts were completed in two 468 consecutive days, beginning with a random starting location and direction of 469 travel. In 2009, counts were conducted continuously from upstream to 470 downstream, so that they could be completed in one day. In each year, a 471 running count of shad nets was made by checking each floating net buoy 472 encountered during these counts to confirm that an actively fishing net was 473 present. Nets that did not comply with published fishing regulations were 474 included in all net count totals, but were not reported to law enforcement until the 475 end of the season to prevent any potential bias in fisherman behavior. 476 For each month of each season, CPUE was obtained using a combination 477 of direct observations of net retrievals and log books from five to seven commercial fishermen. The individual fishermen selected to provide this 478

479 information were chosen based on the river section where they fished and their willingness to participate in the study. Specific locations of their nets were 480 481 independent of each other and interspersed throughout the study area. Each 482 fisherman was compensated US\$500 annually in return for their cooperation in 483 allowing us to observe randomly selected net pulls and for keeping accurate log 484 books of both effort and catch. Direct observations of fishermen were 485 randomized with some allowance for the individual schedules of each. 486 Fishermen were not compensated, however, until accuracy of log books had 487 been verified at the conclusion of each fishing season. Accuracy of log books 488 was verified using two methods: 1) using a matched-pair t-test to compare days 489 when observers were and were not present, and 2) using a matched-pair t-test to 490 identify any significant differences of effort and catch data in log books versus 491 those obtained through direct observations.

Direct observations of catch were conducted at least three times for each participating fishermen during each shad season. During each observation, we followed the fishermen to his nets in a separate boat so that we could record the number of each species captured as the net was retrieved. After all nets had been pulled, we recorded soak times, net dimensions, and mesh sizes. During 2008 and 2009, we also recorded total length (TL) and weight (g) of each shortnose sturgeon that was captured.

499 Data Analysis

500 To estimate total annual effort, we first calculated the mean number of 501 nets fished in each stratum for each month of the season. Total net-hours was

then calculated for each month based on the number of nets counted each week and the total number of fishing hours that the season was open. This included 12 hours for opening and closing days and 24 hours for all other days. Total monthly fishing effort for each stratum was then calculated using the formula: Total fishing effort (net hrs) = Σ ((Mean nets observed / mo) x (Total fishing hrs / mo))

508 Accuracy of log book data from each fisherman was evaluated using a 509 one sample matched-pair t-test ($\alpha = 0.05$) to compare the mean of the 510 differences between days when observers were and were not present. We then 511 used a one sample matched-pair t-test ($\alpha = 0.05$) to compare the mean of the differences between logged and observational data. To perform this test, the 512 513 total annual number of shortnose sturgeon observed in the catch of each 514 individual fishermen was standardized to the total number of net-hours recorded 515 in his log book to calculate a monthly CPUE for each fisherman. Estimates of 516 total monthly effort and catch were then calculated for each fisherman by 517 supplementing the direct observational data with those from the log books 518 recorded on days when observers were not present. A total monthly CPUE for 519 shortnose sturgeon (SNS) was then estimated for each stratum using the 520 formula:

521 CPUE = (Number SNS observed + number SNS logged) / Total net hrs 522 The variance of each of these estimates was used to calculate 0.95 confidence 523 intervals. Assuming a linear relationship between effort and catch, we then 524 estimated total monthly bycatch in each stratum using the formula:

525 Total monthly catch = (Total fishing hrs / mo) x (Mean monthly CPUE) To identify any potential bias of mean CPUE calculations and to evaluate 526 the accuracy of CPUE variance estimates, we resampled our original data using 527 528 bootstrap analysis with replacement as described by Efron and Tibshirani (1994) 529 using SAS (SAS Institute, Cary, NC). We constructed resample sets of both 100 530 and 1,000 bootstrap samples to compare resampled means and variances to 531 those of the original data. For each month in each year in each stratum, we 532 randomly constructed 100 and 1,000 bootstrap samples containing the same 533 number of observations as the year-month-stratum data from which we were 534 resampling (e.g. from 70 field observations we generated 100 and 1,000 535 bootstrap resample sets with 70 observations each). For example, because the 536 original data from the lower stratum in January 2007 contained i = 70 537 observations, each bootstrap sample in the resample sets for the lower stratum 538 in January 2007 also contained i = 70 observations. We then calculated the 539 mean of each bootstrap sample and used these means to calculate grand means 540 and variances for the resample sets (by year-month-stratum, both 100 and 1,000 541 bootstrap samples) for comparison with original field data.

542

543 Results

544 During each of the three commercial fishing seasons sampled, we 545 conducted a total of 7-12 net counts totaling 1,358-2,328 rkm sampled annually. 546 We also collected catch data from 192-336 direct observations, and 10,382 – 547 15,410 net hours of log book entry data (Table 1). From these data, we

estimated that the total anchored gill fishery was comprised of 13-20 fishermen
annually. Of these participants, 2-4 operated in the upper stratum compared to
11-16 in the lower stratum. Over the three fishing seasons, data collected from
log books and direct observations annually accounted for 48% – 66% of all
fishing effort in the anchored gill net fishery (Table 1).

Total estimated effort for the entire anchored gill net fishery varied from 553 554 22,689 - 27,405 hours annually (Table 2). Weekly effort varied from 6 - 35 nets 555 per week during all three years of the study (Figure 2). In the upper river, fishing 556 effort peaked in February of each year; however, effort was not consistent among months or years in the lower river (Figure 2). In the upper river, mean weekly 557 558 effort ranged from 0.8 - 4.0 nets per week. Mean weekly effort in the lower river 559 varied from 14.0 – 28.7 nets per week (Figure 2). Monthly effort varied from 495 560 1536 hours in the upper river compared to 5,712 – 11,700 hours in the lower 561 river (Table 2). Despite this variability, several spatial and temporal trends in 562 bycatch were evident. Most fishing effort (56.3%) occurred between rkm 35 -563 100; however, most bycatch occurred in the upper river. In fact, we estimate that 564 more shortnose sturgeon were incidentally captured in the upper river during 565 January 2009 (333 fish) than in all months of all three years combined in the 566 lower river (216 fish; Table 2).

567 Analysis of log book data from all three years showed that catch data 568 recorded on days when observers were present was not significantly different 569 than on days when observers were absent (p > 0.61 for all three years). 570 Furthermore, total catch of shortnose sturgeon recorded during direct

observations was not significantly different than that provided in fishermen log
books (p > 0.42 for all three years).

Total estimated bycatch varied from a low of 53 shortnose sturgeon in 2008 to 498 shortnose sturgeon in 2009 (Table 2). We estimated that 387 shortnose sturgeon were incidentally captured in the upper river during the 2009 shad season. No bycatch was recorded in the upper river in March during all three years of the study. In 2008 and 2009, bycatch peaked in February in the lower river (36 and 74 fish, respectively), and then declined in March (Table 2). This trend was not observed in 2007, however.

580 During months when shortnose sturgeon were incidentally captured in the 581 upper river, CPUE was always higher than that of the lower river (Figure 3). For 582 example, in January 2009, CPUE in the upper river was 0.5007 SNS/hr,

583 compared to only 0.0015 SNS/hr in the lower river (Figure 3). During February

584 2007 and 2009, CPUE in the upper river was also higher (0.0126 and 0.0512

585 SNS/hr, respectively) than during the same period in the lower river (0.0019 and

586 0.0110 SNS/hr, respectively; Figure 3). During 2008 and 2009, CPUE in the

587 lower river was lowest in January, followed by an increase of over 100% in

588 February, and then a decline in March (Figure 3).

589 Bootstrap results of both the 100 and 1,000 resample sets showed that 590 the observed mean CPUE values for our study were unbiased (Table 3). The 591 associated standard errors for the randomized bootstrap sample sets were 592 smaller than those of the estimated mean CPUE for both strata, indicating that

the variance estimates of mean CPUE in both strata were also accurate (Table3).

Except for one juvenile fish captured in the upper river during January 2009, all shortnose sturgeon we observed during 2008 - 09 measured ≥ 590 mm TL. Most fish appeared to be in healthy condition and swam away after release, however, we were unable to assess any sublethal or post-release effects of incidental capture. Only 4 of the 172 shortnose sturgeon captured in commercial gill nets were dead upon net retrieval, yielding a mortality rate of 2.3% (Table 2).

602 Discussion

603 The results of this study provide the first quantified estimate of annual 604 bycatch and mortality of shortnose sturgeon in the anchored gill net commercial 605 shad fishery of the Altamaha River. Although shortnose sturgeon were captured 606 during all three years of the study, a key finding of this study was that bycatch 607 varied by as much as 900% across years. During the 2007 and 2008 seasons, 608 fewer than 40 shortnose sturgeon were observed in the commercial catch, but in 2009, we recorded 105 captures yielding an expanded estimate of 498 captures 609 610 over the entire three month fishery. Because of stochastic variables in habitat 611 conditions and the protracted spawning periodicity of shortnose sturgeon, we 612 caution against future researchers forming conclusions about sturgeon from 613 short-term data.

614 The Altamaha River is thought to have the largest shortnose sturgeon 615 population among southern rivers; however, the adult abundance is low

616 compared to that of northern river systems. Throughout the study, all but one 617 fish observed in commercial nets were adults (\geq 590 mm TL). A recent study by 618 Peterson and DeVries (2006) showed that the Altamaha population contains 619 1,500-2,000 adults, so we can estimate that in 2009 between 19 and 49 percent 620 of the adult population was "caught" in a net. In southern rivers, females spawn 621 every 3-5 years, and males every 1-2 years. We estimated that 470 (95% Cl 622 278-686) adult shortnose sturgeon were captured in January and February, 623 suggesting that 25 to 80 percent of the spawning run was captured. The 624 observed mortality rate of 2.3% is lower than the 16% previously observed by 625 Collins et al. (1996) in southern shad fisheries. However, studies on sub-lethal 626 and post-release effects of bycatch are lacking. Because incidental capture of 627 spawning adults has been shown to negatively affect spawning behavior, bycatch 628 has indirect population level effects (Moser and Ross 1995; Weber 1996). 629 The highest bycatch rates occurred in the upper river strata, during the month of February. In this stratum, there were never more than five fishermen 630 631 operating at any one time; however, many of their nets were fished in known 632 spawning areas of shortnose sturgeon. During January 2009, we observed 633 several net retrievals in this reach of the river in which 4-16 shortnose sturgeon 634 were captured in one net. In total, 36 adult shortnose sturgeon were recorded in 635 the upper river during January and February 2009, and many of the males were 636 running ripe. In contrast, no sturgeon were captured in the upper river during 637 March in any year, suggesting that the spawning period was probably limited to a 638 four to six week interval lasting from mid-January to late-February.

639 In all three years of the study, few shortnose sturgeon were captured in 640 the lower river in January. Previous telemetry studies by Peterson and DeVries 641 (2006) suggest that spawning shortnose sturgeon have already reached their 642 spawning grounds by the start of the commercial fishing season while non-643 spawners remain in the esturary. Although many shortnose sturgeon were 644 captured in the lower river during 2009, CPUE of shortnose sturgeon in the lower 645 184 km of the river was only 0.0015 compared to 0.5007 in the upper river during 646 the same period. These findings suggest that spawning adult shortnose 647 sturgeon are highly vulnerable to incidental capture in the upper 30 km of the 648 Altamaha River.

649 Reducing bycatch of shortnose sturgeon in commercial fisheries is a 650 critical component of recovering populations throughout the Atlantic coast. 651 Further studies are needed in southern rivers, including the Altamaha, to quantify 652 both direct (mortality) and indirect (sub-lethal and post-release) population level 653 effects of bycatch on shortnose sturgeon populations. Although several potential 654 management strategies already exist to minimize bycatch, the results of this 655 study suggest that river-specific research and monitoring programs are needed 656 to provide quantified data on the spatial and temporal variation in shortnose 657 sturgeon movements for implementation of an effective adaptive fisheries 658 management plan. For example, Collins et al. (2000) suggested the 659 establishment of riverine and estuarine reserves that are completely closed to 660 commercial gill net fisheries. Although closure of critical habitats may or may not 661 be an important component, our results suggest that on the Altamaha River,

delaying the opening of commercial shad fishing in the upper river stratum until 1 March, would almost completely eliminate bycatch of migrating shortnose sturgeon with only a minimal (5-15%) impact of total shad landings (Bahn et al. 2010). Regardless of which specific management actions are used, an adaptive approach that incorporates real-time monitoring of commercial bycatch is the only reasonable means of adequately protecting shortnose populations exposed to commercial gill netting operations. Although complete closure of shad fisheries is probably unnecessary, the annual variability of shortnose sturgeon spawning runs and commercial fishing behavior will preclude any type of "one size fits all" management approach. Consequently, future efforts to minimize shortnose sturgeon bycatch while maintaining the economic and social benefits provided by commercial fisheries will require close cooperation among federal and state management agencies as well as commercial fishermen.

8 Running Title: Juvenile Atlantic Sturgeon

859

860

861 Abstract

862 Juvenile Atlantic sturgeon remain in natal rivers for several years prior to out-migrating 863 to marine environments during later portions of their life history. Data regarding river-resident 864 juvenile population dynamics are unknown. During the summers of 2004 - 2007, we performed 865 mark-recapture of juvenile Atlantic sturgeon in the Altamaha River to assess age-specific 866 abundance, apparent survival, per capita recruitment, and factors influencing recruitment. The 867 objectives of this study were to estimate age-specific abundance, overall juvenile recruitment and 868 apparent survival, and to determine factors influencing recruitment. Estimates indicated that 869 juvenile abundance ranged from 1072 - 2033 individuals, and age-1 and age-2 individuals 870 comprised greater than 87% of the juvenile population, while abundance of age-3 or older 871 individuals was less than 13% of the population. Estimates of apparent survival and per capita 872 recruitment from Pradel models indicated that the juvenile population experienced high annual 873 turnover, as apparent survival rates were low (< 33%) and per capita recruitment was high (from 874 0.82 to 1.38). Fall discharge, which had a positive relationship with recruitment, was the only 875 factor assessed that significantly explained time variation in per capita recruitment. The findings 876 of this study suggest that juvenile populations at the southern extreme of the Atlantic sturgeon's 877 range may remain in natal rivers for less time than northern counterparts. This is further 878 evidence of difference in life history between northern and southern populations of Atlantic 879 sturgeon. Potential findings of density dependence could have major implications for both 880 population recovery and management of this species.

884 Introduction

885 Atlantic sturgeon (Acipenser oxyrinchus) are a long-lived, anadromous species that spend 886 the early portion of their juvenile stage in freshwater (Scott and Crossman 1973). Adults inhabit 887 marine environments in most years, but females enter coastal rivers for spawning every 3-5888 years while males spawn every 1-5 years (Smith 1985). In southern rivers females typically 889 spawn by age-10 and males by age-8 (Smith 1985), but age at maturity in northern populations 890 may require 20 years or more (Scott and Crossman 1973). Spawning occurs well upriver from 891 the saltwater interface of most rivers (Van Eenennaam et al. 1996, Caron et al. 2002, Hatin et al. 892 2002), as embryos and larvae are intolerant of salinity (Van Eenennaam et al. 1996). At 893 hatching, embryonic Atlantic sturgeon seek cover within interstitial spaces of rocky substrates, 894 but after 8 - 10 d they emerge as true larvae and disperse downstream (Kynard and Horgan 895 2002). Larval migration continues for approximately 12 d, and although most movements occur 896 at night during the first 6 d, little diel preference has been observed thereafter (Kynard and 897 Horgan 2002). In early juvenile development, individuals primarily use deep water habitats near 898 the fresh/saltwater interface (Moser and Ross 1995, Bain 1997). After 2 – 6 years in these 899 habitats, juveniles leave their natal rivers for marine environments (Dovel and Berggren 1983). 900 Throughout their range, Atlantic sturgeon populations have suffered declines resulting from decades of anthropogenic activities. Throughout much of the 20th Century, adults were 901 harvested during spring spawning migrations for both meat and caviar (Smith 1985). As northern 902 903 stocks declined, commercial fishing shifted to southern rivers, particularly during the 1970s and

904 1980s (Colligan et al 1998). While overexploitation was likely a primary cause of most 905 population declines, habitat degradation may be impeding or limiting recovery of many 906 populations (Smith 1985). Degraded water quality from industrial effluents and poor land use 907 practices has adversely affected spawning and nursery habitats throughout the species' range 908 (Smith 1985, Colligan et al. 1998). Especially in southern rivers, thermal effluents and excessive 909 ground water pumping often degrades juvenile habitats by increasing water temperatures and 910 lowering dissolved oxygen (Rochard et al. 1990, Collins et al. 2000, Niklitscheck and Secor 911 2005).

912 Although Atlantic sturgeon have been federally protected since 1996 (ASMFC), 913 recovery has been difficult to assess because (1) historical abundance data are largely lacking, 914 (2) the cryptic and complex life cycle of the species makes quantitative assessments difficult, and 915 (3) latitudinal variation in ecology and population dynamics confounds direct comparisons of 916 data from northern and southern river systems. Despite uncertainties regarding recruitment mechanisms and other basic aspects of juvenile ecology, long-term monitoring of juvenile 917 918 abundance (i.e. recruitment) is currently one of the most critical research needs for assessing 919 species recovery (Atlantic Sturgeon Status Review Team. 2007). In the Hudson River for 920 example, Peterson et al. (2000) estimated abundance of age-1 juveniles to demonstrate the 921 severity of recruitment declines resulting from decades of overfishing. Unfortunately, those authors relied on the presence of hatchery-reared juveniles to estimate the abundance of wild 922 923 juveniles, an experimental approach which may not be appropriate or even possible on other 924 rivers systems. Furthermore, studies of recruitment mechanisms in Atlantic sturgeon have not 925 been attempted in any Atlantic coast river system.

926 While both scientists and managers agree that quantified methods of assessing sturgeon 927 recruitment are essential for evaluating population trends and identifying key environmental 928 factors that affect year class formation, early life stages of most sturgeon species are notoriously 929 difficult to sample. In both freshwater and estuarine environments, juvenile sturgeons are widely dispersed and/or invulnerable to most types of sampling gear. Consequently, quantified 930 931 estimates of abundance and mortality of juvenile sturgeons have persisted as critical information 932 gaps in our understanding of recruitment mechanisms of sturgeon stocks worldwide (Pine et al. 933 2001, Secor et al. 2002; Peterson et al. 2006). Recently, however, some notable successes have 934 been obtained using both empirical data and modeling methods. For example, Pine et al. (2001) 935 used age-structured models to estimate first year survival in Gulf sturgeon. In a field study of 936 lake sturgeon on the Peshtigo River, Wisconsin, Caroffino et al. (2010) sampled eggs, larvae, and age-0 juveniles to estimate first-year survival. Similar studies have been completed for a 937 938 few other species, but quantified estimates of post-recruit juveniles are lacking. The Altamaha River, Georgia is currently thought to contain the 2nd largest population of Atlantic sturgeon in 939 940 US waters (Peterson et al. 2008, Atlantic Sturgeon Status Review Team. 2007), but unlike the 941 Hudson River, recruitment studies of Atlantic sturgeon have not been attempted there. The 942 objectives of this study were to: 1) estimate annual age-specific abundance, 2) estimate annual 943 apparent survival and per capita recruitment and 3) identify key factors that influence 944 recruitment processes of juvenile Atlantic sturgeon in the Altamaha River.

945 Methods

946 Study Site/Fish Sampling

947 The study was conducted entirely within the tidally influenced portion of the Altamaha
948 River system, near Darien, Georgia (Figure 1). To ensure spatial distribution of sampling

949 locations, specific sampling sites were randomly distributed within three contiguous 10-km strata 950 compromising the lower 30 rkm of the Altamaha Estuary. Within each stratum, channel habitats 951 deeper than 3 m were sampled weekly from June to August, 2004 – 2007. Juvenile Atlantic 952 sturgeon (Ages 1-3+) were captured using both trammel nets and experimental gill nets 953 measuring 91 m by 3 m. Experimental gill nets consisted of three 30.5-m panels of 7.6, 10.2, 954 and 15.2-cm monofilament mesh (stretch measure). Trammel nets were made from 7.6-cm mesh 955 inner panel and two 30.5-cm mesh outer panels. Nets were deployed perpendicular to the 956 current, anchored to the bottom, and fished for 25 - 90 min during slack tides only. 957 As nets were retrieved, juvenile Atlantic sturgeon were removed and placed in a floating 958 net pen, where they were allowed to recover for 10-15 minutes prior to data collection. Each fish 959 was then checked for PIT tags using a portable PIT tag reader. If no tag was detected, one was 960 injected beneath the fourth dorsal scute. Measurements of total length (mm) and weight (kg) 961 were then recorded for each fish. Prior to release a 0.5 - 1.0-cm section of the leading pectoral 962 fin spine was removed from a random sub-sample of 32 and 25 fish in 2005 and 2006 963 respectively for subsequent age determination.

964

965 Data Analysis

Ages of juvenile Atlantic sturgeon were determined based on modal distributions of length-frequency histograms as described by Peterson et al. (2000) and subsequently, by McCord et al. (2007). Accuracy of modal distribution age assignments was verified from fin spines sections collected from a random sub-sample of captured juveniles. Using the basic methods described by Cuerrier (1951), pectoral fin spine sections were first air dried for at least one

971 month, cross-sectioned using a Beulher Isomet[®] low-speed saw, and viewed under a dissecting
972 scope to reveal growth annuli.

973

974 Modeling Overview

975 The modeling approaches used to meet the objectives of the study involved the use of 976 robust design based model types. Traditional robust design models implement a combination of 977 open and closed model types (Kendall et al. 1995). Open population models, such as the 978 Cormack-Jolly-Seber model (or CJS; Cormack 1964, Jolly 1965, Seber 1965), are used between 979 primary occasions that are widely spaced, such as annual sampling, to provide estimates of 980 apparent survival. Apparent survival is defined as the probability of an individual surviving and 981 remaining in the study are during the interval from time i to time i + 1. Within primary occasions, 982 a series of sampling events, known as secondary occasions, are taken at shorter intervals, days or 983 a week, when the population is assumed closed, allowing the use of traditional closed population 984 abundance estimators (Otis et al. 1978). The assumptions of the traditional robust design are as 985 follows:

986 1. The conditional probability of surviving from primary period i to i + l is the same for 987 all fish

9882. The conditional probability of being caught at each primary period is the same for all989 marked fish

990 3. The fates of fish with respect to survival and capture are independent

- 991 4. Marks are retained and correctly recorded
- 5. Sampling periods are instantaneous, or very short, and recapture fish are releasedimmediately

- 994
- 6. All emigration is permanent
- 9957. Within primary periods, the population is closed to birth, death, immigration, and996emigration

997 Two different modeling approaches were used to address the objectives of the study. 998 Robust design models have been modified to incorporate multi-state models among primary 999 periods, enabling the use of traditional closed capture models to estimate state specific 1000 abundance within primary periods, while allowing for state transitions between primary periods 1001 (Kendall and Bjorkland 2001, White et al. 2006). The closed robust design multi-state model 1002 type helped address the first objective by allowing us to estimate capture and recapture 1003 probabilities, determine factors influencing these probabilities, and therefore estimate state-1004 specific abundance. The Pradel robust design model was used to estimate apparent survival, per 1005 capita recruitment, and factors influencing recruitment. Per capita recruitment was defined as 1006 the number of new juveniles in the population at time i per juvenile in the population at time i - i1007 1. This is a relatively simple extension of the traditional robust design, where a Pradel model is 1008 used between primary periods rather than a CJS. Age-specific abundance estimates were not 1009 used to estimate these parameters because of potential for biased estimates. Both error in the age 1010 determination process and violations of assumptions could lead to biased age-specific abundance 1011 estimates, making them less useful than the direct estimates from the Pradel model. The 1012 assumptions of the Pradel robust design model are the same as the traditional robust design. 1013 We used a closed robust design multi-state model to estimate annual age-specific 1014 abundance and to identify factors influencing capture and recapture probabilities. Individual 1015 capture histories were constructed by using each sampling week during the summer as an

1016 individual sampling period. Eight secondary periods (4 weeks in June, and 4 weeks in July)

1017 within four primary periods (summers of 2004 - 2007) yielded a total of 32 sampling periods. 1018 Captured juveniles were first categorized into three different age strata; age-1, age-2, or age-3+. 1019 We then used the Huggins formulation of the multi-state robust design model (Huggins 1989; 1020 1991) to estimate annual abundance of each age class. The closed robust design multi-state 1021 model assumes the population is closed (i.e. no birth, death, immigration, emigration, or state 1022 transitions) within primary periods (summers), but open between primary periods. By using age 1023 as a state within the model, we were able to estimate annual abundance of each age class, while 1024 quantifying the effects of weekly sampling effort, water temperature, and river discharge on 1025 capture and recapture probabilities.

1026 A candidate set of models with different combinations of parameters for capture and 1027 recapture probabilities was constructed to identify potential differences among age-classes, 1028 behavioral responses, and to quantify influences of environmental predictor variables. Apparent 1029 survival and state transition probabilities were modeled as constant across time and ages in all 1030 models. Capture and recapture probabilities were modeled either as constant or as functions of 1031 predictor variables specific to secondary period sampling. Sampling effort was measured as 1032 number of nets set per week. Weekly means in water temperature and discharge were included as 1033 key environmental variables. Water temperature data were obtained from the Georgia Coastal 1034 Ecosystem – Long Term Ecological Research (GCE-LTER) monitoring station (~rkm 14, in 1035 South Altamaha River), while discharge data were obtained from the United States Geologic 1036 Survey (USGS) gauging station at rkm 100 (#02226000). All predictor variables were 1037 standardized, with a mean of zero and a standard deviation of one, across years before 1038 incorporation into models. The effects of predictor variables on capture and recapture 1039 probabilities were modeled as either constant or varying among summers. Behavioral response

to capture (increased or decreased recapture rates after initial capture) was evaluated by
including all models in the candidate set with capture and recapture probabilities set equal. To
test for potential heterogeneity in capture and recapture probabilities among age classes, all
models in the candidate set were rerun with separate parameters for each age class.

The relative likelihood of each model was evaluated with an information theoretic approach (Burnham and Anderson 2002), by calculating Akaike's information criterion (Akaike 1973) with a small sample size adjustment (AICc; Hurvich and Tsai 1989). As survival and state transition probabilities were consistent among models, assessing model likelihoods allowed us to identify sources of variation in capture and recapture probabilities. The most plausible model was then used for age-specific abundance estimates, with the corresponding parameterization of capture and recapture probabilities used in subsequent models to assess juvenile recruitment.

1051 Pradel temporal symmetry models with robust design were used to estimate parameters 1052 specific to the entire juvenile population (Kendall et al. 1995, Pradel et al. 1996). Open mark-1053 recapture models are conditioned on first capture and use observed capture histories to estimate 1054 apparent survival and recapture probability. Reverse time models are conditioned on last 1055 observation of individuals and the reverse capture history is used to estimate the probability of an 1056 individual being in the population at a prior time (known as seniority probability) and 1057 recruitment of new individuals. Pradel temporal symmetry models use both forward and reverse 1058 time approaches simultaneously to estimate recruitment, population growth, and seniority 1059 probability (Pradel 1996). Like the closed robust design multi-state model, the Pradel robust 1060 design model also assumes the population is closed within primary periods (summers), but open 1061 between primary periods. Incorporation of Pradel models between primary periods (summers of

2004 – 2007) of robust design models was used to estimate apparent survival, per capita
recruitment, and juvenile population abundance.

Per capita recruitment was defined as the number of new juveniles in the population at time *i* per juvenile in the population at time i - 1. Apparent survival was defined as the probability of an individual surviving and remaining in the river during the interval from time *i* to time i + 1. Apparent survival was modeled as constant or time varying. Capture and recapture probabilities were modeled using the same parameters as the best approximating closed robust design multi-state model.

1070 A candidate set of models with different combinations of recruitment parameters was 1071 constructed to evaluate the effect of various predictor variables on annual variation in juvenile 1072 recruitment. The candidate set also included models with recruitment time varying without 1073 predictor variables. Predictor variables used to explain annual variation in recruitment included 1074 spawner abundance and seasonal averages of water temperature and river discharge at time of 1075 age-0. Mean water temperature and discharge during March – May (spring), June – August 1076 (summer), and September – November (fall) were used as predictor variables because seasonal 1077 changes in flow and temperature have been previously recognized as important variables 1078 influencing Atlantic sturgeon recruitment (Secor and Gunderson 1998). Estimates of spawner 1079 abundance were derived from previous assessments of adult abundance by Peterson et al. (2008). 1080 All predictor variables were standardized among years, with a mean of zero and standard 1081 deviation of one.

As in closed robust design multi-state models, the relative plausibility of each model was determined with an information theoretic approach (Burnham and Anderson 2002). Models with recruitment predictor variables were only considered important if they were more plausible than

time varying recruitment models lacking a predictor variable. As model weights were dispersed among several models, model-averaged parameter estimates were used to account for model selection uncertainty (Burnham and Anderson 2002). Model-averaged estimates and unconditional standard error were calculated for both the apparent survival and recruitment parameters and juvenile population abundance estimates.

- 1090
- 1091 Results

1092 In the four consecutive years of study, a total of 1,034 juvenile Atlantic sturgeon were 1093 tagged in a total of 391 net sets. A total of 86 individuals were recaptured at least once (Table 1094 1). During summer sampling, water temperature and discharge varied only slightly among years, 1095 except in 2005 when river discharge was higher and water temperature was lower. In all other 1096 years, summer water temperatures remained near 30° C and discharge varied from 70.5 to 154.6 1097 m^3 /s. Average number of nets set in a sampling week varied from 11.6 to 13.3 among sampling 1098 years. Catch-per-unit-effort varied from 2.04 to 3.75 juveniles per net from 2004 - 2007. Sizes 1099 of captured juveniles varied from 350 - 1050 mm total length, although 90% of juveniles 1100 measured less than 714 mm (Figure 2). While relative abundance of juvenile age-classes varied 1101 annually, the size distribution of juveniles within year classes was similar in each year of the 1102 study.

Length frequency analyses of the catch identified a distinct modal distribution of juveniles. Length frequency analyses combined with age-determination from the random subsample of fin spines confirmed that age-1 juveniles measured 350 – 550 mm, age-2 juveniles measured 550 – 800 mm, while age-3+ juveniles measured 800 – 1050 mm (Figure 3). These results were consistent among all years of the study, except 2007 where the boundary between

1108age-2 and age-3+ individuals was estimated to be 750 mm. After assigning ages to all juveniles1109captured in each year, we calculated that the total catch from 2004 to 2007 was comprised of 5681110age-1, 403 age-2, and 63 age-3+ juveniles (Table 2). Although annual abundance of the total1111juvenile population ranged from a low of 1,072 in 2004 to a high of 2,033 in 2006, ages 1-21112comprised 87-96% of the juvenile population in all years of the study.1113Closed robust design multi-state models revealed the best-fitting model had capture and1114recapture probabilities equal and as a function of weekly effort varying annually (Table 3).

1115 Model comparisons showed that this model was 10.5 times more plausible than the second best 1116 model, which also had capture and recapture probabilities equal but as a function of temperature 1117 varying annually. These analyses indicated that there was no significant behavioral response to 1118 capture, and there was no evidence that capture and recapture probabilities differed among age 1119 groups.

1120 The best-fitting Pradel model indicated survival was time varying and that annual 1121 recruitment was significantly influenced by fall discharge, which had a positive relationship with 1122 recruitment (Table 4; Figure 4). In fact, this model was 1.69 times more plausible than the 1123 second best model, which had survival and recruitment time varying with no predictor variables. 1124 The third ranked model included recruitment as a function of spring Schnabel adult abundance 1125 estimates, but as this model was less likely than time varying recruitment lacking a predictor 1126 variable, it was not considered to be important. Model averaged parameters from Pradel models 1127 indicated that apparent survival and per capita recruitment estimates varied annually, with 1128 highest recruitment of 1.379 occurring in 2005 and highest apparent survival of 0.338 in the 1129 interval prior to 2006 (Table 5).

1130

1131 Discussion

Length-frequency histograms were combined with ages determined from fin spines 1132 collected from randomly selected juveniles to estimate the ages of captured juveniles. There 1133 1134 were some discrepancies between age determinationmethods. Ages determined from fin spines 1135 suggested that age-1 individuals could reach lengths of 600 mm; however, the length-frequency 1136 histograms from those years showed several distinct, non-overlapping modes. Because the modal distributions of age-1 juveniles predicted a maximum length of 550 mm for that age 1137 1138 group, we used 550 mm as the upper limit for defining age-1 cohorts. This same approach was used by Peterson et al. (2000) who found that age-1 Atlantic sturgeon in the Hudson River were 1139 always <550 mm through the month of August (the end of our sampling season). Regardless, 1140 1141 setting maximum size of age- cohorts in this study at 600 mm would only have changed the age 1142 assignment of a few individuals. As both approaches are subject to error, by combing length 1143 frequency analyses with fin spine collection we hoped to minimize any potential bias in our age 1144 estimates. Furthermore, average length at age-1 of Altamaha juveniles was virtually identical to 1145 that of age-1 juveniles from coastal rivers in South Carolina (McCord et al. 2007). Although 1146 these results suggest that age-estimates from length-frequency histograms and fin spines can be 1147 used to accurately identify age-1 cohorts in other southern rivers, spatial and temporal variations 1148 in growth could potentially complicate age assignment for older juveniles. Hence, future studies 1149 using known age juveniles, possibly from hatchery origin, are needed to validate age estimates of 1150 juveniles > age 2.

1151 Closed robust design multi-state models provided estimates of age specific juvenile 1152 abundance and identified potential sources of variation in capture probability. Model results 1153 showed that individuals of all age classes were equally likely to be captured or recaptured. The

analyses also confirmed the accuracy of the estimates by demonstrating that heterogeneity in capture probability was minimal, and hence, did not bias the abundance estimates. Consequently, we suggest that similar modeling approaches be used for other Atlantic sturgeon populations, so that results can be compared with those presented here. Provided that adequate numbers of juveniles can be captured over several consecutive years, such comparisons will greatly improve current knowledge of recruitment trends in many river systems.

1160 The use of Pradel robust design models allowed for direct estimates of apparent survival 1161 and per capita recruitment, which together revealed a high turnover rate of the juvenile 1162 population. Apparent survival estimates were low, ranging from 0.03 to 0.34. Given that 1163 Atlantic sturgeon are a long lived species (Scott and Crossman 1973), low apparent survival 1164 values were most likely most caused by high rates of out-migration rather than true mortality. 1165 Per capita recruitment estimates in this study ranged from 0.82 to 1.38, indicating that annual 1166 recruitment to age-1 was nearly equal to, or greater than, the abundance of the entire juvenile 1167 population in the preceding year. Likewise, apparent survival was lowest when recruitment was 1168 highest, suggesting that a higher percentage of age-2 and older juveniles leave the river in years 1169 when newly recruited age-1 fish are more abundant. The surprisingly high turnover rate of 1170 river-resident juveniles observed in this study is consistent with findings of previous studies 1171 suggesting that the temporal scale of Atlantic sturgeon life history of is condensed in southern 1172 populations (Van Den Avyle 1984, Smith 1985,) compared to those of northern rivers where 1173 adults mature later and live longer (Scott and Crossman 1973, Van Eenennaam 1996). These 1174 findings also suggest that out-migration of river-resident juveniles older than age-1 may be 1175 influenced by density dependence. The source of density dependence could be competition with 1176 younger cohorts. Because early juveniles are intolerant of salinity, they are likely unable to seek

1177 alternative foraging habitats in coastal waters if riverine food resources become limited. Older 1178 iuveniles, however, have no such constraints, but may prefer the relatively predator free 1179 environments of brackish water estuaries as long as food resources are not limited. To our 1180 knowledge, no research on competition among cohorts for river food sources has been 1181 researched in Atlantic sturgeon. Although further studies are needed, confirmation of density 1182 dependence in river-resident juvenile Atlantic sturgeon would have major implications for 1183 understanding ontogenetic variations in growth, survival, migration rates, and recruitment to 1184 marine life stages.

1185 Obtaining separate estimates of annual survival and out-migration rates was not possible 1186 in this study. In using the open population models to estimate apparent survival of juvenile 1187 cohorts in the Altamaha river, the requisite assumption was that emigration of juveniles was 1188 permanent (Williams et al. 2002). Consequently, apparent survival represented the probability of 1189 any individual surviving after time i and remaining in the river until time i + l. As apparent 1190 survival was confounded by permanent emigration, mark-recapture methods were not capable of 1191 providing separate estimates of annual survival and out-migration, yet these rates are critical in 1192 understanding recruitment processes for the species. Future studies are needed to obtain 1193 quantified recruitment data using alternative methods such biotelemetry and known-fates 1194 modeling approaches (Cox and Oakes 1984).

Although we examined the potential effects of several environmental variables, fall discharge was the only predictor variable that significantly explained annual variation in annual year class strength. The most plausible model was that with fall discharge as a predictor of recruitment, but the model with time-variation but no predictor variables also carried substantial relative weight. The fact that a model with time-variation but no predictor variables was the only

1200 other model to carry relative weight could indicate that other time varying factors not addressed 1201 in this study are important to the recruitment process. Adult abundance from the proceeding 1202 spring was the next best predictor variable, but these models were less likely than those with 1203 time varying recruitment lacking a predictor variable. Recent studies of Gulf sturgeon on the 1204 Suwannee River suggest that mean river flow during September and December may be 1205 positively related to recruitment of age-0 juveniles (Randall and Sulak 2007). The authors 1206 speculate that increased flow in fall and early winter may help increase dissolved oxygen and 1207 reduce salinity, thereby increasing potential foraging habitats available to age-0 juveniles. Given 1208 the number of hydro-generating facilities currently located on Atlantic coast rivers, future studies 1209 addressing the effects of flow on year class formation in Atlantic sturgeon should be considered 1210 as a high priority for long-term restoration of the species.

1211 The results of this study provide the first quantified recruitment data of a juvenile 1212 Atlantic sturgeon population in a southern river. Although further studies are needed to better 1213 understand recruitment mechanisms and variables affecting out-migration of river-resident 1214 juveniles, our results show that stage-based projection or population viability models can be used 1215 to assess population recovery of Atlantic sturgeon in the Altamaha and other Atlantic coast 1216 rivers. Similar approaches have been used in previous studies of other sturgeon species to 1217 project population trends (Pine et al. 2001), to identify survival bottlenecks at specific life history 1218 stages (Paragamian et al. 2005), and to quantify survival rates necessary to achieve recovery 1219 goals (Morrow et al. 1998). With regard to Atlantic sturgeon, however, current demographic 1220 data are needed to complete similar analyses. The results of this study provide quantified 1221 estimates of age-1 recruitment, apparent survival, and age-specific abundance, all of which could 1222 be used in simplified population viability analyses.

1223 Despite the difficulties sampling juvenile sturgeons in large river systems, quantified 1224 recruitment data are essential to monitoring population recovery and to better understand the 1225 environmental variables that affect juvenile survival. Because juvenile Atlantic sturgeon remain 1226 in their natal rivers for at least 2 years after birth, quantified estimates of age-1 juveniles may 1227 offer the best opportunity to obtain these data. Similar approaches also may be possible for 1228 other sturgeon species, but the field methods employed must be developed based on a thorough 1229 understanding of specific life history traits and seasonal habitat needs. Thorough assessment of 1230 population status and recovery will require proper sampling designs and statistical approaches. Although future studies of sub-adult and adult life stages are needed, quantified assessment of 1231 1232 river-resident juveniles can provide fisheries managers with the current data needed for 1233 evaluating population trends. Previous studies of Atlantic sturgeon on the Altamaha River have 1234 shown that population inference based on adult spawning runs can be confounded by the 1235 presence of non-spawning adults and immature fish (Peterson et al. 2008). The results of this 1236 and other studies show that sampling of river-resident juveniles, particularly the age-1 cohort, can 1237 provide reliable estimates of recruitment, a key aspect of evaluating population recovery (Bain et 1238 al. 1999, Peterson et al. 2000). The importance of monitoring juvenile populations is further 1239 supported by the finding that adult abundance does not accurately reflect variation in juvenile 1240 recruitment.

Based on current regulations, areas open to commercial shad fishing in Georgia are highlighted in purple.

391-2-4-.02 Commercial Shad Fishing.

(1) **Purpose.** The purpose of these Rules is to implement the authority of the Board of Natural Resources to promulgate rules and regulations based on sound principles of wildlife research and management, establishing the seasons, days, places and methods for fishing commercially for shad.

(2) Areas Open to Commercial Shad Fishing.

(a) Nets shall be set or fished only in flowing water within the banks of the stream channels. Nets may not under any circumstances be set or fished in waters that are not flowing such as in sloughs or dead oxbow lakes.

(b) Waters of the Savannah River system open to commercial shad fishing are the Savannah River downstream of the U.S. Highway 301 bridge, Collis Creek, Albercorn Creek, Front River, Middle River, Steamboat River, McCoy's Cut, Housetown Cut, Back River upstream from Corps of Engineers New Savannah Cut, New Savannah Cut, North Channel Savannah River downstream to a line running due south of the easternmost tip of Oyster Bed Island, South Channel Savannah River downstream to a line running from the southeast tip of Cockspur Island to the mouth of Lazaretto Creek, and Elba Island Cut between North and South Channels of the Savannah River.

(c) Waters of the Ogeechee River system open to commercial shad fishing are the Ogeechee River downstream from Georgia Highway 204 bridge, Hell's Gate cut, and Ossabaw Sound upstream from the sound/beach boundary (see 391-2-4-.03) to a line running from the northwest tip of Raccoon Key across buoy R "86" to the southernmost tip of marsh adjacent to Green Island.

(d) Waters of the Altamaha River system open to commercial shad fishing are the Ohoopee River upstream to the U.S. Highway 1 bridge; the Altamaha River downstream of the from U.S. Highway 1 bridge including Cobb Creek Oxbow, Beards Creek from its mouth upstream to the Long-Tatnall County line (Big Lake), Sturgeon Hole from the Altamaha River to the lower mouth of Harper Slough, Old Woman's Pocket, South Branch, General's Cut, South Altamaha River, Champney River, Butler River, One Mile Cut, Wood Cut, Darien River upstream to the confluence Darien Creek and Cathead Creek, Buttermilk Sound upstream to the mouth of Hampton River, Hampton River, Altamaha sound to the sound/beach boundary (see 391-2-4-.03), Rockdedundy River, Little Mud River, South River, Back River, North River upstream to a line from range F1 R4 sec A across buoy R "178" to Sapelo Island. Old River and Mid Slough of the Penholoway River and Ellis Creek are closed to commercial shad fishing.

- (e) Reserved.
- (f) Reserved.

(3) Seasons. The commercial shad fishing season shall be open as provided in subparagraphs (a), (b) and (c) of this paragraph from 1 January to 31 March; however, the Commissioner of Natural Resources, in accordance with current, sound principles of

wildlife research and management, may at his discretion open or close the season 30 days after 31 March on any or all areas open to commercial shad fishing.

(a) The Altamaha River system downstream from the Seaboard Coastline Railroad bridge (at Altamaha Park) will be open to commercial shad fishing Monday through Friday each week. Upstream of this point will be open Tuesday through Saturday each week.

(b) The Savannah River system downstream from the I-95 bridge will be open to commercial shad fishing Tuesday through Friday each week. Upstream of the I-95 bridge it will be open Wednesday through Saturday each week.

(c) The Ogeechee River system will be open to commercial shad fishing Friday of each week.

(4) Gear and Methods for Taking Shad.

(a) Commercial Shad Fishing Gear.

1. Set nets and drift nets of at least four and one-half inch stretched mesh or trot lines (in accordance with O.C.G.A. 27-4-91) may be used to commercially fish for shad, provided, however, that only drift nets may be used in the Savannah River system downstream of a line between the mouth of Knoxboro Creek and McCoys Cut at Deadman's Point; the Ogeechee River; Altamaha Sound; and Doboy Sound.

2. Nothing in this section shall preclude the commercial use of pole and line gear as identified in O.C.G.A. 27-4-35.

(b) Methods for Taking Shad.

1. Set nets must be placed at least six hundred (600) feet apart and shall be limited to one hundred (100) feet in length. All set nets must have one end secured to the stream's bank and be buoyed at the outer (streamward) end so as to be clearly visible to boaters.

2. Set and drift nets must be situated so as to follow one-half the stream width open and free for the passage of fish.

3. Drift nets shall not be fished closer than three hundred (300) feet apart and shall be limited to a maximum of one thousand (1,000) feet in length in saltwaters.

Authority O.C.G.A. Title 27. History. Original Rule entitled "Commercial Shad Fishing" adopted. F. Dec. 28, 1979; eff. Jan. 17, 1980. Amended: F. Dec. 28, 1983; eff. Jan. 17, 1984. Amended: F. Dec. 2, 1987; eff. Dec. 22, 1987. Amended: F. June 19, 1989; eff. July 9, 1989. Amended: F. Dec. 9, 1994; eff. Dec. 29, 1994. Amended: F. Nov. 4, 2010; eff. Nov. 24, 2010.

Georgia Commercial Shad Fishery Regulation Options

The Georgia Department of Natural Resources (GA DNR) implemented new commercial shad regulations for the 2011 shad season. This action was taken in response to recent study findings that illustrated that potentially significant numbers of shortnose sturgeon could be incidentally captured in shad gill nets and the adoption of Amendment 3 to the Atlantic States Marine Fisheries Commission's (ASMFC) Interstate Fisheries Management Plan for Shad and River Herring. GA DNR utilized the best available data, results from Bahn and Peterson (2010) and GA DNR's commercial landings data, when evaluating changes to the commercial shad regulations. Bahn and Perterson's (2010) research analyzed the commercial shad set-net fishery in the Atlamaha River from 2007-2009. Results from this study revealed that during 2007-2008 the bycatch rates of shortnose sturgeon in this fishery were relatively low, however, during 2009 by catch rates of shortnose sturgeon greatly increased in the upper section of the Altamaha River. Factors, such as the periodic spawning behavior of sturgeon, location of potential spawning sites in the upper section of river, and environmental conditions (i.e. water level), may have all contributed to the increase in catch rates observed in 2009. In an attempt to reduce shortnose sturgeon bycatch in Georgia's commercial shad fishery and comply with Amendment 3 mandates, the following options were considered:

Option 1:

No change to existing commercial shad regulations. However, a status quo approach would not have provided any additional conservation measures for shortnose sturgeon nor satisfy mandates outlined in ASMFC's Amendment 3. Therefore, this option was not selected.

Option 2:

Establish new upper boundaries for commercial shad fishing on the Altamaha and Savannah rivers, while the Ogeechee, Satilla, and St. Marys rivers would have been completely closed to commercial shad fishing. It is believed that such actions would have provided adequate protection for shortnose sturgeon and satisfied Amendment 3 mandates. However, this option was not chosen due to the negative economic impacts that a total closure would have had on Ogeechee River commercial shad fishermen.

Option 3 (Preferred/Chosen Option):

Establish new upper boundaries for commercial shad fishing on the Altamaha, Ogeechee, and Savannah rivers and completely closed the Satilla and St. Marys rivers to commercial shad fishing. It is believed that these actions will provide adequate conservation measures for shortnose sturgeon and satisfied ASMFC Amendment 3 mandates.

The new upper boundary for the Altamaha River was set at the U.S. Hwy 1 bridge crossing and effectively closed commercial shad fishing on approximately 75% of the free flowing portions of the Altamaha River and it's major tributaries (Ocmulgee and Oconee rivers). According to results reported by Bahn and Peterson (2010), this would decrease estimated sturgeon bycatch by up to 78% while only decreasing Altamaha River shad set-net landings by approximately 9%.

Other upper boundaries for the Altamaha River were considered (confluence of the Ohoopee River, U.S. Highway 84 bridge, and the Seaboard Coastline Railroad bridge). Utilizing 2009 creel estimates from Bahn and Peterson (2010), moving the upper boundary to one of these

lower points revealed minimal reductions in estimated shortnose sturgeon bycatch beyond those expected by setting the boundary at the U.S. Hwy 1 bridge, while having greater impacts to the commercial shad fishery. Due to the relatively small conservation advantages and larger impacts to the commercial shad fishery, GA DNR chose to set the upper commercial shad fishery boundary at U.S. Hwy 1.

No recent data on shortnose sturgeon bycatch was available for the Savannah and Ogeechee rivers. However, based on the findings from the Altamaha River it was presumed that closing the upper portions of these rivers would also likely provide greatly increased protection to shortnose sturgeon, while having relatively little impact on the commercial shad fisheries in these rivers. The upper commercial shad fishery boundary on the Savannah River was set at the U.S. Hwy 301 bridge crossing and resulted in closure of approximately 47% of the free flowing portion of the Savannah River. On the Ogeechee River, an upper commercial shad fishery boundary was established at the GA Hwy 204 bridge, which closed approximately 80% of the 245 miles of free flowing river. The number of days that the Ogeechee River remained open to commercial fishing was also reduced by 50% to one day per week and gear was limited to drift net only.

GA DNR does not have any reports off commercial shad landings on either the Satilla or St. Marys rivers since 1989. Therefore, it was concluded that entirely closing these two rivers would protect sturgeon in these two rivers and have no impact on commercial shad fishermen.

٩
